⑤④ X-ray radiography system.

⑤⑦ A method and device for producing flux equalized x-ray images for medical radiography through the use of a scanning fan shaped x-ray beam and a feedback control system which regulates the beam intensity at a multiple number of points along the fan beam to compensate for the x-ray attenuation variations of the patient.

**FIG. 1.**

## X-Ray Radiography Method and System

### Technical Field

This invention relates to a device and method of producing feedback controlled flux equalized x-ray images with the principal application being in medical radiography.

### Background Art

Frequently, the dynamic response range of an x-ray imaging system is less than the x-ray attenuation range of the object to be imaged. This situation is encountered often by the conventional x-ray radiography system, which is comprised of a film-screen cassette as the detector-recorder for x-ray images and an x-ray source with a broad and spatially uniform beam. This system has been in popular use since the discovery of x-rays about ninety years ago. The medical x-ray film typically has a very high contrast enhancement factor, which is often called the contrast gradient or gamma, resulting in a very narrow latitude (or exposure range). This high contrast enhancement factor is a necessary feature of an x-ray film because typical anatomical objects to be detected have very low x-ray contrast so that their image on the x-ray film would be too faint for the physicians to see if the contrast enhancement factor were lowered.

In most x-ray examinations, such as a chest examination, the typical patient exhibits very large anatomical thickness variations and, thus, very large x-ray attenuation variations. That is, some anatomical parts are very opaque to x-rays and some other parts are very transparent to x-rays. As a result, x-ray films of these examinations, due to the narrow exposure range of the x-ray film, are optimally exposed for only a portion of the entire picture, leaving large portions of the picture either overexposed or underexposed. The contrast enhancement factor for both the overexposed and the underexposed regions is much lower than that of the optimally exposed regions. Therefore, there is significant loss of x-ray information (and loss of diagnostic value) in the overexposed and underexposed regions of the x-ray film.

For example, in a typical PA chest film, the lung field is usually optimally exposed by choice, and the mediastinal and subdiaphragmatic areas are left underexposed. The probability of detecting tumors and other abnormalities located in the underexposed areas is significantly lower than the detection probability in the lung field, where the exposure is optimum. This non-uniform exposure of

the x-ray film, which is due primarily to the large thickness variations in a typical patient, is a major shortcoming in conventional x-ray radiography systems. The image quality and diagnostic value of the x-ray film can be improved significantly if the non-uniform exposure effect caused by these thickness variations in the patient can be reduced.

Indeed, Pennington et al (Proc. SPIE, volume 233, pages 176-182 (198)), Plewes et al ((A) Radiology, volume 142, pages 765-768 (1982); and (b) Diagnostic Imaging, October 1985, pages 85-96), and others have demonstrated that nodule detection in chest films can be significantly improved with some compensating means by which the non-uniformity in the exposure is reduced. These compensating means all involve spatial modulation of the x-ray flux so that the flux at the x-ray film is more or less equalized. The process is frequently called the flux equalization method.

In order to provide flux equalization to all varieties of patients, feedback controls have to be added to the flux equalization processes. That is, flux equalization is provided after some spatial attenuation information has been obtained on the specific patient who is being examined. It is important to point out here that in carrying out the feedback controlled flux equalization process, one must not generate new problems such as patient motion unsharpness resulting from prolonged exposure time, artifacts from compensation misregistration, increased patient dosage, excessive heat loading on the x-ray tube target, increasing the effect of scattered x-rays, and user of patient inconveniences.

There exists a large body of feedback controlled flux equalization prior art. Representative of the prior art using a x-ray mask are U.S. Patents No. 3,755,672 (Edholm et al) and No. 4,497,062 - (Mistretta et al). Representative of the prior art using an optical mask is U.S. Patent No. 4,322,619 (Nelson et al). Prior art using a raster scanned x-ray target to generate a scanning pencil beam of x-rays is represented by U.S. Patent No. 2,837,657 - (Craig et al). Prior art using a mechanically moved scanning aperture to generate a scanning pencil beam of x-rays is represented by Plewes et al - (Medical Physics, volume 10, pages 655-663 - (1983)). Prior art using a scanning fan beam are represented by U.S. Patent No. 4,433,430 - (Fredzell) and Plewes et al (Radiology, volume 142, pages 765-768 (1982)).

The most pertinent prior art related to the present invention are feedback controlled flux equalization x-ray radiography systems using a scanning fan beam of x-rays. Representative of the

prior art are, as mentioned above, U.S. Patent No. 4,433,430 (Fredzell) and an article by Plewes et al - (Radiology, volume 142, pages 765-768 (1982)). The main advantages of these systems over the systems using the scanning pencil beam of x-rays are: (a) increased x-ray tube life with about 10 to 20 times reduction in heat loading through more efficient use of x-rays, (since heat loading is proportional to the ratio of the area of the imaged field to the area of the scanning aperture and the aperture used in scanning fan beam is usually 10 to 20 times larger than the aperture used in scanning pencil beam,) (b) less patient motion problem through shorter time required to complete the imaging process, (c) less scan artifacts because scanning pencil beam systems require accurate control of the spacing between overlapping scan lines and the size and profile of the x-ray spot, and (d) less cooling time of the x-ray tube associated with reduced heat loading means shorter wait between examinations and higher patient throughput.

The scanning fan beam systems also have many advantages over the systems using x-ray or optical masks. These advantages are: (a) no need of hassle in the making and subsequent registration or alignment of x-ray or optical masks, (b) much less patient misregistration problem resulting from much less time delay between the process of obtaining the patient attenuation information and final imaging process, and (c) much better rejection against scattered x-rays.

However, the main drawback of the fan beam systems taught by Fredzell and Plewes is that the flux equalization is only applied in the direction of the scan and not in the direction perpendicular to the scan. That is, the feedback signal is used to control the x-ray source intensity or duty cycle providing an uniform x-ray intensity across the entire fan beam. This one-dimensional feedback controlled flux equalization is unable to provide compensation to the entire image and is also prone to scan artifacts. Indeed, Plewes et al concluded in the same article that a scanning pencil beam system is the "only" way to overcome this drawback. The system taught by Fredzell has two fan beams. One fan beam is used as the monitoring beam to acquire patient attenuation information, and the second fan beam is used to image. However, since the same x-ray source is being used by both fan beams and the source intensity modulation would also affect the monitoring fan beam, it is not clear how the system's feedback control could function properly. It should also be obvious that Fredzell's systems could not support more than one imaging beam since each imaging beam would require a different modulation.

## Summary of the Invention

The above and other problems of x-ray fan beam type feedback controlled flux equalization imaging are overcome by the present invention of a scanning x-ray fan beam flux equalization system incorporating a dynamic feedback controlled flux modulation array means so that the x-ray intensity at a multiple number of points along the fan beam can be modulated in accordance with the need to compensate for the patient attenuation along the fan beam (in the direction perpendicular to the direction of the scan). The flux equalization system is interposed, for the most part, between the fan beam source and the imaging device and comprises a detector array located behind the patient for detecting the x-ray intensity transmitted through the patient at a multiple number of points along the fan beam and for generating an output signal representative of the detected x-ray intensity at such points, an x-ray flux modulator array located between the x-ray source and the patient for modulating the intensity of the x-ray fan beam at a multiple number of points along the fan beam in response to a control signal, and a feedback control circuit for processing the detector signal and then supplying the appropriate control signal to the flux modulator array to cause it to increase or decrease the x-ray flux at a multiple number of points along the fan beam until a substantially equal and predetermined flux level is detected by the detector.

In the preferred embodiment of this invention, the flux modulation is accomplished by modulating the local width of the fan beam with a movable shutter in the direction of the scan during the exposure at a multiple number of points across the fan beam. That is, the fan beam width is very broad over "thick" patient regions where the patient attenuation is very high, and the fan beam width is very narrow over "thin" patient regions where the patient attenuation is very low.

This method of flux modulation has two unique advantages. The first advantage is that the x-ray spectrum is essentially unchanged over the "thin" patient regions. This is not the case in Edholm et al and Mistretta et al. Their x-ray masks are made of x-ray absorbers which compensate for the patient attenuation in such a way that a thin absorber is used over the "thick" patient regions and a thick absorber is used over the "thin" patient regions. In this fashion, the soft component of the x-ray spectrum is preferentially removed (or the x-ray beam is hardened) from the "thin" patient regions where the soft component is needed the most to provide increased image contrast. The second advantage is that the effective exposure time over "thin" patient regions is very much shortened by the narrower fan beam width. Therefore, the patient motion prob-

lem in the "thin" patient regions, where the patient motion is most problemsome, is reduced. The local beam width modulation is not permitted in the scanning pencil beam devices of Craig et al and Plewes et al, because the pencil beam aperture size has to be held constant. Accordingly, this advantage allows the fan beam device to operate at an exposure time 10 to 20 times shorter than the pencil beam devices in "thin" patient regions.

The present invention retains all the advantages of fan beam feedback controlled flux equalization systems over the other feedback controlled flux equalization systems discussed in the sections above. It is a faster real time system as well as a more effective system with respect to the utilization of x-rays than the scanning pencil beam systems and is less susceptible to scan artifacts. Therefore, this invention is less susceptible to patient motion problems and also requires less heat loading to the x-ray tube. In addition, this invention has much better rejection against scattered x-rays than the x-ray mask systems of Edholm et al and Mistretta et al.

In another embodiment of this invention, several parallel scanning fan beams are used in unison so that the utilization of x-rays is further improved and the heat loading to the x-ray tube is further reduced. In a modification of this embodiment, the first scanning fan beam is used as a monitoring precursor beam and the trailing fan beams are flux equalized imaging fan beams. The monitoring fan beam used only to collect the x-ray attenuation data at a low dose. The trailing imaging fan beams get the modulation signal from the feedback computer based on the data collected by the monitoring fan beam. Since the monitoring fan beam and the imaging fan beams are identical in construction, spatially well aligned with each other, and with short exposure time delays between the fan beams, the misregistration problems and patient motion problems are insignificant. This approach also uses fewer components and hence is lower in construction cost, because the monitoring beam does not need a flux modulator and all the trailing imaging beams do not need detector arrays.

It is therefore an object of the present invention to provide, in an x-ray radiography system, essentially real time feedback controlled flux equalization to the x-ray image recorder.

It is another object of the present invention to provide, in an x-ray radiography system, flux equalization without substantially altering the x-ray spectrum.

It is another object of the present invention to provide, in an x-ray radiography system, flux equalization with shorter exposure time to "thinner" regions of the patient.

It is another object of the present invention to provide, in an x-ray radiography system, flux equalization with increased rejection to scattered x-rays from the patient.

It is yet another object of the present invention to provide, in an x-ray radiography system, flux equalization with a minimum increase of heat loading to the x-ray tube.

It is yet a further object of the present invention to provide, in an x-ray radiography system, flux equalization with reduced patient motion problems, scan artifacts, and patient inconvenience.

These features and advantages of the present invention will become more apparent upon a perusal of the following specification taken in conjunction with the accompanying drawings wherein similar characters of reference refer to similar structures in each of the separate views.

#### Brief Description of the Drawings

Figure 1 is a diagrammatic, perspective view illustrating a first embodiment according to the invention;

Figure 2 is a diagrammatic, sectional view, taken generally along the lines 2-2 in Figure 1;

Figure 3 is a diagrammatic, sectional view, taken generally along the lines 3-3 in Figure 1;

Figure 4 is a diagrammatic, vertical, sectional view of a second embodiment of the invention;

Figure 5 is a diagrammatic, vertical, sectional view of a third embodiment of the invention;

Figure 6 is an enlarged vertical, sectional view, with portions broken away, in the flux modulator of a fifth embodiment of the invention;

Figure 7 is an enlarged, perspective view, with portions broken away and in section, of a flux modulator according to a sixth embodiment of the invention; and

Figure 8 is an enlarged vertical, sectional view, with portions broken away, of a flux modulator according to a seventh embodiment of the invention.

#### Best Mode for Carrying out the Invention

Referring now more particularly to Figures 1, 2 and 3, an x-ray source 10 generates a broad x-ray beam 5 which impinges upon a first collimator 12 having a horizontal slot shaped aperture 14 for converting the x-ray beam 5 into a broad fan beam 7 which impinges upon a patient 18. Behind the patient is a second collimator 20 having a corresponding horizontal slot shaped aperture 22 which is aligned with the aperture 14. The collima-

tor 20 substantially blocks patient scattered x-rays 19 from reaching the imaging panel 24. Aligned with the aperture 22 is an array 26 of individual detectors 28 which can be either x-ray detectors or photo-optic detectors depending upon the particular application. Interposed between the detector array 26 and the collimator 20 is the x-ray imaging panel 24 which can be either x-ray film-screen cassette or storage phosphor cassette or Xerox cassette or other panel shaped image recorder, in which case the detectors 28 are x-ray detectors or it could be an x-ray image intensifier device optically coupled to film or TV camera or other image pick-up devices in which case the detectors could be photo-optic detectors.

The collimators 12 and 20 as well as the detector array 26 are connected together mechanically as indicated by the dashed line 32 to a motor drive 34. It is also equally feasible to drive these three elements with separate encoded motors to move in synchronism. Since such scanning apparatus is well known by those skilled in the art, it will not be described in further detail.

The outputs of the detectors 28 of the array 26 are fed to a closed loop feedback circuit 30 whose output controls a flux modulator 16 positioned over the aperture 14 of the first collimator 12. The feedback control circuit 30, in response to the output signals from the detectors 28, automatically reduces the x-ray flux passing through the aperture 14, by means of the flux modulator 16, so as to maintain a substantially equal and constant x-ray flux level at the input of the detectors 28, along the x-ray beam. Furthermore, this flux control is a dynamic process which is continually changing as the collimators 12 and 20 and the detector array 26 scan the body of the patient 18.

It is to be understood that when the term "equal flux level" is referred to it is not meant that at each minute point the x-ray flux exiting the patient is equal. Were this condition true, no diagnostic information would be available to the physician. Rather what is meant is that the average flux for a series of hypothetical "windows", whose areas correspond to the area covered by each detector (or a group of detectors), is equal across the fan beam. Within each such hypothetical window the x-ray flux will vary, depending on the x-ray image information.

Referring now more particularly to Figure 6, a portion of one form of a flux modulator is illustrated. As can be seen in Figure 2, the flux modulator 16 is made up of a group of individual cells 17 which are arrayed across the x-ray beam 5 coming from the source 10. Each cell 17 preferably corresponds to a portion of the x-ray beam which will impinge on one or more corresponding detectors 28 of the array 26. In order for a particular cell 17

to control the amount of x-ray flux striking a corresponding detector 28, it is necessary to reduce the cross-sectional area of the x-ray beam 5 by reducing the local width of the fan beam as it scans over the patient.

Thus, as shown in Figure 6, each cell comprises a shutter 36 which is movable across the input of the aperture 14 of the collimator 12 to restrict the cross-sectional area of the x-ray beam 5. The shutter 36 is made of an x-ray opaque material, such as lead or tungsten or other metal and is operated by a servo motor 38 which receives its control signal either in digital or analog form from the feedback control 30. It will be understood that each cell 17 is provided with its own independent shutter 36 and servo motor 38 which operates under the control of the feedback circuit 30 responding to an output signal of a corresponding detector 28.

As the x-ray flux reaching a particular detector 28 increases above the preset standard value, the output of the detector will increase in magnitude and this increase will be fed back through the circuit 30 to the servo motor 38 of the corresponding flux modulation cell 17 aligned with that particular detector 28. This increase in the detector output signal will be transformed into a corresponding repositioning of the shutter element 36 to narrow the aperture 14 at the particular location across the x-ray beam. This will decrease the amount of x-ray flux accordingly until the output of the corresponding detector 28 reaches a predetermined reference level representative of the desired flux level.

Alternatively, the servo motor 38 can drive the shutter 36 into and out of the path of the beam 5 to turn the beam on for a desired duration or number of times at a higher frequency than the scan frequency (which is the number of apertures to cover the image field divided by the total scan time). This will in effect control the duty cycle of the beam and thus control the net amount of flux received both by the patient and by the corresponding detector 28. In this case, the duration or duty cycle of the beam on time is under the control of the output of the corresponding detector in the same manner as described above until the desired flux level is detected. That is, an increase in the output of the detector will cause the duration or duty cycle of the beam on time of the shutter 17 to increase until the output of the corresponding detector 28 is equal to the predetermined reference level.

Referring now more particularly to Figure 7, a cell of a different type of modulation unit is depicted. In this system instead of a shutter blade 36 which is interposed into the path of the x-ray beam 5, a plurality of fingers 40 for each shutter blade replaced are individually inserted across the aperture 14. These fingers protrude from a electro-

mechanical device 42, similar to a dot matrix printhead as used in a computer printer. Each finger is individually addressable in digital or analog fashion by the feedback control 30 in response to the output signal of a corresponding detector 28, in the manner described above in reference to Figure 6.

Depending on the particular mechanism 42 utilized, the position of the fingers 40 can be discretely controlled or, in other embodiments, the fingers can be either inserted or removed from the path of the beam. In the first version, the extent of the total number of fingers into the beam determine the effective width of the aperture 14 at that flux modulation cell and thus the flux level. In the second modification, the number of fingers interposed into the beam versus the number of open spaces determines the flux level. In still a third modification, the duration at which the fingers are extended into and removed from the beam is controlled by the feedback control 30. Again, the duty cycle of the fingers within the beam determines the flux level in the manner described above in reference to a single shutter of Figure 6.

The fingers 40 are made of an x-ray opaque material. Thus any portion of the x-ray beam which impinges upon the fingers will be effectively stopped and any portion of the x-ray which does not impinge upon the fingers will pass through to strike the patient and the detector array 26. The significant feature of all of the flux modulations schemes discussed above is that for the portion of the x-ray beam which passes through the aperture there has been no change in the x-ray spectrum. Thus low energy x-rays, which are generally needed to enhance the detection of low density tissues in the more transparent regions of the patient, such as the lung region, are not reduced or removed, thereby contributing to the diagnostic efficacy of this device.

Referring now to Figure 4, another embodiment of the present invention is illustrated. In this embodiment, a plurality of x-ray fan beams are used in unison to improve the utilization of x-rays and to decrease the heat loading on the x-ray. Each of the fan beams in this embodiment is constructed and operates substantially the same as the single fan beam described above and illustrated in Figures 1, 2, and 3. As illustrated in Figure 4, each fan beam 7a has its own corresponding slots 14a and 22a in collimators 12 and 20, flux modulator array 17a, detector array 26a, and feedback control circuit 30a.

In the case of Figure 4, where three x-ray fan beams are depicted, the scan of the image can be accomplished in two different ways. One way is to scan the entire image field once with all three fan beams and with the x-ray tube operating at one-third of the rating required by the single fan beam

system. Another way is use each fan beam to scan only one-third of the image field by spacing the fan beams at one-third of the image field width apart. In this way, the total scan time is reduced by a factor of three as compared to the total scan time of the single fan beam system. Both scan methods are capable of reducing the x-ray tube heat loading by approximately a factor of three, which equals the number of fan beams used.

Referring now more particularly to Figure 5, another embodiment of the invention is illustrated. In this embodiment a plurality of fan beams are used again in unison to improve the utilization of x-rays, but the first fan beam (or the leading fan beam in the direction of scan) has been modified to be used as a monitoring precursor beam for the sole purpose of collecting the x-ray attenuation information at a low dose. As shown in Figure 5, a plurality of imaging fan beams 7a, 7b, which are defined by the corresponding horizontal slot apertures 14a, 14b in the collimator 12, are modulated independently by flux modulator arrays 17a and 17b. These imaging fan beams are further collimated through the horizontal slot apertures 22a and 22b in the collimator 20 before impinging on the imaging panel 24.

Additionally, a low intensity x-ray monitoring fan beam 44, which is defined by a narrower horizontal slot aperture 14c in the collimator 12, is used with a detector array 26 to measure the x-ray attenuation of the patient. The detector array 26 is positioned immediately behind the horizontal slot aperture 22c in the collimator 20 and in front of the imaging panel 24. In all other respects the device depicted in Figure 5 is constructed and operates substantially the same as that depicted in Figure 4 with the following exceptions.

The collimators 12 and 20 are operated synchronously to scan the monitoring beam 44 over the entire length of the patient 18. However, the x-ray imaging beams are not only modulated in intensity by the modulation arrays 17a and 17b they are also turned on to only scan the upper and lower halves of the patient 18, respectively. Thus, in operation, the collimators 12 and 20 are positioned so that the monitoring beam 44 starts at the top of the head of the patient 18 (or it could also scan from the bottom to the top or from side to side as the case may be). The flux level information revealed by detecting this monitoring beam is collected by the detector array 26 and is stored in the feedback control computer 30 relative to the scan position of the aperture 22c.

As the collimators 12 and 20 reach the point where a line drawn between the apertures 14a and 22a would just intersect the top-most portion of the patient 18 (or whatever other portion of the patient 18 constitutes the beginning of the imaging scan),

the flux modulator arrays 17a and 17b are both opened to allow the x-ray image beams 7a and 7b to scan the patient 18. However, the flux modulator arrays 17a and 17b are operated under the control of the feedback computer 30 so that the flux modulation cells across the beams 7a and 7b are controlled to pass only the correct amount of x-ray flux and equal flux density is obtained at the screen 24. The computer 30 scans its memory bank for the stored output signals from the detector array 26 corresponding to the position of the x-ray beams 7a and 7b as they scan the patient. These signals are then used to control the flux modulators 17a and 17b as the image beams 7a and 7b scan over the same points on the patient's body that were previously scanned by the monitoring beam 44.

The scanning by the collimators 12 and 20 stops when the x-ray image beam 7b has reached the bottom of the patient 18. The spacing between the apertures 14a, 14b and 14c and between the apertures 22a, 22b and 22c is chosen so that there will be no overlapping of the scanning beams 7a and 7b in scanning the patient 18. Obviously, in other embodiments, more than two image scanning beams could be utilized in the same manner as described above in reference to the beams 7a and 7b.

This approach uses fewer components and is lower in construction costs than the embodiment described in reference to Figure 4, because the monitoring beam does not need a flux modulator and all the trailing imaging beams do not need detector arrays. The fact that the monitoring fan beam does not have to perform imaging duties allows the detector array 26 to be conveniently placed in front of the imaging panel 24. This improvement in the placement of the detector array provides more freedom in the designs of the imaging panel as well as additional savings in the construction costs. Since the monitoring fan beam and the imaging fan beams are identical in construction, specially well aligned with each other, and with short exposure time delays between the monitoring and image fan beams, the misregistration problems and patient motion problems are insignificant.

Referring now more particularly to Figure 8, still a further alternative flux modulation cell is illustrated. In this modification the shutter 80, corresponding to the shutter 36 depicted in Figure 6, is also controlled by a servo motor 38 which receives its control signals from the feedback circuit 30. Shutter 80 is wedge-shaped and is made of a material which attenuates x-rays passing through it. Thus the position of the wedge-shaped shutter 80 with respect to the aperture 14 controls the flux density of the x-ray beam 5 passing through it. As the portion of the wedge which intercepts the beam 5 is thicker, at one side of the wedge, more of the

x-ray beam will be attenuated than if only the thin portion of the wedge is intercepted by the beam 5. This embodiment has the disadvantage that low energy x-rays are disproportionately attenuated in the "thin" regions of the patient.

More detailed considerations of the fan beam geometry and the flux modulator mentioned in the above embodiments will now be given. In order to obtain a reasonable x-ray utilization efficiency as well as good rejection against scattered x-rays, the size of the fan beam at the imaging plane (the plane of imaging panel 24) should be approximately between 10 mm to 40 mm in width (W) and 432 mm in length (G) for standard chest x-ray examinations. The width of the fan beam is proportional to the x-ray utilization efficiency and is inversely proportional to the x-ray tube heat loading required to perform the imaging scan, whereas the width of the fan beam is inversely proportional to the ability to reject scattered x-rays.

The flux modulator should be placed close to the x-ray source so that the fan beam width at the modulator (or the distance which the shutter blades have to cover during the modulation process) is small. However, if the modulator is placed too close to the x-ray source, the x-ray penumbra due to the finite size of the x-ray source (focal spot) becomes too large at the imaging plane and the equalization process becomes too gross (spatial frequency becomes too low) to be useful. For the above reasons, the ratio of the distance (D) between the flux modulator and the imaging panel to the distance (d) between the flux modulator and the x-ray source spot (focal spot) should be in the range of 5 to 25. That is,

$$\frac{D}{d} = 5 \text{ to } 25.$$

For a practical x-ray focal spot (f) of 1.0 mm, the corresponding range of x-ray penumbra size (P) at the imaging plane for this range of placement of the flux modulator is 5 to 25 mm. That is,

$$p = f \left( \frac{D}{d} \right).$$

For a fan beam with a width (W) of 22 mm, the range of the fan beam width at the flux modulator (w) is 3.67 to 0.85 mm, which is the distance to be covered by the shutter blades. That is,

$$w = W \left( 1 + \frac{D}{d} \right).$$

In order to minimize sources of scan artifacts, the width (s) of the shutter blades should be sufficiently small so that its x-ray shadow on the imaging plane is within a factor of two from the size of the x-ray penumbra due to the focal spot size. That is,

$$s \approx f \left( \frac{(D/d)}{(D/d+1)} \right).$$

Since the length ( $g$ ) of the fan beam at the flux modulator is

$$g = G / (1 + \frac{D}{d}),$$

then the number ( $N$ ) of shutter blades in a flux modulator is simply  $g/s$  or

$$N = W / (f \frac{D}{d})$$

For  $W = 432$  mm,  $f = 1.0$  mm, and  $D/d = 10$  to 20, then the number of shutter blades in a flux modulator is in the range of 40 to 20. At about  $D/d = 20$ , the fan beam width at the flux modulator and the shutter blade width are both about 1.0 mm in size and the shutter blade thus has a square looking cross-section with respect to the x-ray beam. At  $D/d$  smaller than 20, the fan beam width becomes larger than the shutter blade width.

The shutter blade 36 can have a square or rectangular cross-section perpendicular to the x-ray fan beam, but the cross-section in the plane of the fan beam can be trapezoidal in order to have a better fit to the shape of the divergent fan beam.

The x-ray absorbing material used in the flux modulator shutter blade 36 as well as the wedge-shaped shutter 80 can be selected from a large number of material groups. For example, the material can be made from a metal or an alloy or a compound containing one or more of the following elements: Pb, Bi, Ta, W, Mo, Ed, Fe, Ni, Cu, Co, Ba, Ce and rare-earth elements.

Each detector element 28 of the scanning detector 26 array can be an x-ray detector diode or it can be made, for example, of a scintillator, such as a rare-earth intensifying screen or a CsI screen or a BGO crystal, or a CdWO<sub>4</sub> crystal, coupled to a silicon diode light detector or a photomultiplier tube. The detector array can also be made of an array of gas ionization cells or a scintillator screen optically coupled, in contact or through a lens or a bundle of fiber optical light pipes, to an array of self scanned silicon diodes or a TV camera. An image intensifier can also be used as a part of the detector system to provide amplified signals.

The detector arrays 26 described in above embodiments are coupled to the fan beams and are moved in step with the fan beams. However, it is equally feasible in certain geometries, such as in the case of planar imaging panels like film-screen cassettes, these detector arrays are replaced by a stationary bank of strip shaped detector elements oriented perpendicular to the plane of fan beam. That is, each detector element 28 is made of a long strip detector with a length equal to the total width of the image field and is aligned with its corresponding flux modulator element 17 during the entire scan. These detector strips are very similar in shape and operation to those long detectors disclosed by Edholm et al (see U.S. Patent No. 3,755,672, column 10, line 51 and Figure 9).

The image recorder 24, for which the flux equalized information is provided, can be a simple x-ray film or a x-ray film-screen cassette. It can also be an automatic film changer or an image intensifier-film or image intensifier-TV system. It can also be a special imaging cassette, which is capable of storing a latent x-ray image for retrieval at a later time.

As explained above, in all of the embodiments, the feedback control circuit 30 derives a signal for the flux modulator based on the detected x-ray transmittance signal through the patient. The product of the x-ray transmittance of the flux modulator and the x-ray transmittance of the patient at any point of the image field must be held to a constant. That is, the transmittance of any one of the elements of the modulator 17 is varied in inverse proportion to the transmittance of the patient at the corresponding point so that the resultant signal received by the corresponding element of the detector 28 is essentially the same as the signal from all other detector elements.

More detail considerations of the systems operation of the present invention will now be given. A conventional radiography system for chest x-rays consists of typically a medium speed film-screen cassette, a 10:1 grid, a photo-timer, and a three-phase 12-pulse x-ray generator operating at 125 Kvp and 400 mA with a source-detector distance of 72 inches. For average patients, the typical exposure time is about 10 milliseconds for PA views and about 30 milliseconds for lateral views.

With a system incorporating only a single fan beam, the present invention will be able to provide feedback controlled flux equalized film with similar local exposure times and better rejection against scattered x-rays. The parameters of the system will be as follows. The size of the fan beam at the imaging plane will be 25 mm in width and 432 mm in length. The  $D/d$  will be about 15 to 20. The total scan time will be about one second. The system will be operated with a medium speed film-screen cassette, a source-detector distance of 72 inches and without a grid. The generator will be operated at 125 Kvp and 150 mA for PA views and 450 mA for lateral views. With multiple fan beams, the system will have more flexibility and less heat loading.

Further improvement in diagnostic value can be obtained from the flux equalized films from the system of the present invention by employing x-ray films, with a gamma larger than 3, with higher contrast enhancement factors. Higher contrast films cannot be used with the conventional radiography systems where already large regions are either overexposed or underexposed.

It is obvious that the scanning of this system can be carried out in any orientation or direction. However, for ease of construction, the direction of scan should be parallel to the spine of the patient 18. However, for better rejection against scattered x-rays, the scan direction should be perpendicular to the spine of the patient. It is also obvious that the present flux equalization invention can be applied to most of the medical radiography examinations as well as to industrial radiography examinations.

The terms and expressions which have been employed here are used as terms of description and not of limitations, and there is no intention, in the use of such terms and expressions, of excluding equivalents of the features shown and described, or portions thereof, it being recognized that various modifications are possible within the scope of the invention claimed.

### Claims

1. X-ray scanning apparatus of the type having an x-ray source for generating a fan beam and for scanning the x-ray fan beam over an object and a detector located on the opposite side of the object for detecting the x-ray flux passing through the object, wherein the improvement comprises:

a detector which includes an array of detectors located across the x-ray fan beam for detecting the x-ray flux passing through the object at multiple points across the fan beam and for outputting electrical signals representative of the detected flux at such points;

an x-ray flux modulator for modulating the intensity of the x-ray fan beam at a multiple number of points across the fan beam;

a feedback circuit supplied with the output electrical signals of the detector array for controlling the flux modulator so as to modulate the flux of the beam at multiple points across it, the full spectrum of the beam being modulated substantially equally at each particular point, so that the flux detected by the array will be substantially equal across the beam.

2. X-ray scanning apparatus as recited in claim 1 wherein the x-ray modulator selectively varies the cross-sectional area of the x-ray fan beam at each of said points to control the flux density.

3. X-ray scanning apparatus as recited in claim 1 further comprising means for creating a visually perceptible image of the x-ray fan beam passing through the object.

4. X-ray scanning apparatus as recited in claims 3 or 13 wherein the imaging means is located between the object and the detector array.

5. X-ray scanning apparatus as recited in claims 3 or 13 wherein the detector array is located between the object and the imaging means.

6. X-ray scanning apparatus as recited in claim 1 wherein the x-ray source simultaneously generates and scans both a monitoring x-ray fan beam and a plurality of imaging x-ray fan beams over the object, the monitoring beam proceeding the imaging beams and wherein the flux modulator separately modulates each imaging x-ray beam at multiple points across it and the detector array scans the object on the side opposite from the x-ray source in alignment with the monitoring beam, the detector array including a time delay circuit for delaying the output signals to the flux modulator to compensate for the difference in time between the passage of the monitoring beam over a particular point and the subsequent passage of the imaging beams over the same point.

7. X-ray scanning apparatus as recited in claims 1 or 13 wherein the flux modulator comprises a plurality of bundles of x-ray opaque rods, the rods being selectively extendable into the path of the x-ray beam in response to the output signals from the detector array.

8. X-ray scanning apparatus as recited in claim 7 wherein each rod bundle is positioned to regulate the x-ray beam flux over a different discrete area of the x-ray beam which impacts on the detector whose output signal controls the position of the rods of that bundle.

9. X-ray scanning apparatus as recited in claim 8 wherein the rods are oscillated into and out of the path of the beam at a rate which is controlled by the magnitude of the output signal of the corresponding detector.

10. X-ray scanning apparatus as recited in claim 8 wherein the rods are extended into the path of the beam to a length which is controlled by the magnitude of the output signal of the corresponding detector.

11. X-ray scanning apparatus as recited in claims 1 or 13 further comprising a prescatter collimator and a postscatter collimator and means for moving both collimators and the detector array in unison and in alignment to sweep over the object.

12. X-ray scanning apparatus as recited in claims 1 or 13 wherein the flux modulator is interposed between the x-ray source and the object.

13. X-ray flux control apparatus for use with an x-ray source for generating a fan beam and for scanning the x-ray fan beam over an object, such as a patient, means for visually imaging the x-ray fan beam passing through the patient, wherein the flux control apparatus comprises:

a detector which includes an array of detectors located across the x-ray fan beam for detecting the

x-ray flux passing through the object at multiple points across the fan beam and for outputting electrical signals representative of the detected flux at such points;

an x-ray flux modulator for modulating the intensity of the x-ray fan beam at a multiple number of points across the fan beam;

a feedback circuit supplied with the output electrical signals of the detector array for controlling the flux modulator so as to modulate the flux of the beam at multiple points across it, the full spectrum of the beam being modulated substantially equally at each particular point, so that the flux detected by the array will be substantially equal across the beam.

14. X-ray flux control apparatus as recited in claim 13 wherein the x-ray modulator selectively varies the cross-sectional area of the x-ray fan beam in the direction of the scan movement of the beam at each of said points to control the flux density.

15. X-ray flux control apparatus as recited in claim 1 further comprising means for dividing the x-ray fan beam into both a monitoring x-ray fan beam and a plurality of imaging x-ray fan beams over the object, the monitoring beam proceeding the imaging beams and wherein the flux modulator separately modulates each imaging x-ray beam at multiple points across it and the detector array scans the object on the side opposite from the x-ray source in alignment with the monitoring beam, the detector array including a time delay circuit for delaying the output signals to the flux modulator to compensate for the difference in time between the passage of the monitoring beam over a particular point and the subsequent passage of the imaging beams over the same point.

16. A method for modulating the flux intensity of an x-ray scanning apparatus of the type having an x-ray source for generating a fan beam and for scanning the x-ray fan beam over an object and a detector located on the opposite side of the object for detecting the x-ray flux passing through the object, wherein the flux modulation method comprises the steps of:

detecting the x-ray flux passing through the object at multiple points across the fan beam and outputting electrical signals representative of the detected flux at such points;

modulating the intensity of the x-ray fan beam at a multiple number of points across the fan beam; and controlling the flux modulator in response to said electrical signals so as to modulate the flux of the beam at multiple points across it, the full spectrum of the beam being modulated substantially equally at each particular point, so that the flux detected by the array will be substantially equal across the beam.

17. The x-ray flux modulation method as recited in claim 16 wherein the modulating step comprises the step of selectively varying the cross-sectional area of the x-ray fan beam at each of said points to control the flux density.

18. The x-ray flux modulation method as recited in claim 16 further comprising the step of imaging the x-ray fan beam passing through the object onto high contrast x-ray film, having a gamma greater than three.

19. An x-ray scanning method comprising the steps of simultaneously generating and scanning both a monitoring x-ray fan beam and a plurality of imaging x-ray fan beams over an object, the monitoring beam preceding the imaging beams, detecting the monitoring beam passing through the object, at multiple points across the monitoring beam in a direction perpendicular to the scan direction and generating output signals representative of the flux magnitude at such points, delaying the output signals to compensate for the difference in time between the passage of the monitoring beam over a particular point and the subsequent passage of the imaging beams over the same point, and separately modulating each imaging x-ray beam at multiple points across the imaging x-ray beam in response to the delayed output signals.
